The detection of deafness in humans is the most accurate method of identifying the genetic cause of disease. The present study was designed to test the hypothesis that vestibular hair cells can be identified on the basis of the amount of efferent-induced motor responses in a genetically deaf mouse model. Male and female C57BL/6 mice of various ages were tested by vestibular coil stimulation with electrical pulses delivered from a modified commutator. A representative motor response was graded from 0 to 4, and responses were graded as present or absent, to determine their sensitivity and reliability in distinguishing genetic types of deafness. Results demonstrated that mice with a point mutation in the GATA3 gene were more likely to respond to vestibular stimulation than normal mice. The results also showed that mice lacking an F3H gene were more likely to respond to vestibular stimulation. These data showed that vestibular responses could provide an objective means of early detection of deafness.Q: Saving a Custom d4474df7b8
